

GSE150430 (Chen et al., Cell Res 2020, PMID 32686767): author-normalised log1p matrix, 48,584 cells, 26 annotated types (25 shown: CAFs excluded, fewer than 5 usable samples). Relative value = cell-type pseudobulk / sample mean; two-sided sign test over samples (A). The 12-gene set is higher in monocytes, macrophages and DC2; for the 134 scheme-A core targets (132 in the matrix) no cell type is significantly above the sample mean (0 of 25 types higher; 21 types are significantly lower at BH q < 0.05, and non-malignant epithelium 1.29 and malignant 1.04 are among the 4 that are not significant). B: random sets of 134 genes matched gene-by-gene on overall expression (20 quantile bins, 10,000 draws, BH over 25 types): relative to such sets the 134 targets are shifted towards monocytes, macrophages, DC2 and non-malignant epithelium and away from lymphocytes, while malignant cells stay within the random range. This is a property shared with expression-matched gene sets drawn from all genes, not tested against other druggable gene sets, and values stay below the sample mean in myeloid cells. NR1H4 is absent from the matrix.
